Appendix — Instruction for Calculating National Public Health Surveillance System Indicators Using 1999 Data — 103

Foreword

The Centers for Disease Control and Prevention (CDC) Injury Center, The Council of State and Territorial Epidemiologist (CSTE), and the State and Territorial Injury Prevention Directors' Association (STIPDA) are pleased to bring you this second edition of the *State Injury Indicators Report* with 1999 data. Twenty-six state health departments voluntarily participated in this surveillance effort. The data inside represent continued progress toward routine surveillance and reporting of injury indicators in all states. This second edition incorporates data from a greater number of states and includes data on the poisoning indicator, with both gender and age-specific rates. The indicators were calculated by using state-level data from death certificates and hospital discharge records coupled with data from several national surveillance systems. As more states join in this surveillance, we can present a broader picture of the burden of injuries and better identify priorities for prevention. We look forward to increased state participation in future reports.

Introduction

Injury surveillance is one of the most important and basic elements of injury prevention and control. It helps determine the magnitude of injury morbidity and mortality, the leading causes of injury, and the population groups and behaviors associated with the greatest risk. Surveillance data is fundamental to determining program and prevention priorities. Furthermore, this data is crucial for evaluating the effectiveness of program activities and for identifying problems that need further investigation.

Fifty-nine million injuries were reported in 1995, resulting in 37 million hospital emergency department visits and 2.6 million hospital discharges. Injuries also accounted for 37% of all hospital emergency department visits, and about 8% of all short-stay hospital discharges. That year, 147,891 people died from injuries: 61% from unintentional injuries, 21% from suicides, and 15% were homicides. Death from injury is the leading cause of years of potential life lost before age 75 in the United States.¹

The mission of public health includes prevention, mitigation, assuring that the injured have access to treatment, and reducing injury-related disability and death.¹ Its scope encompasses injuries involving any mechanism (e.g., firearm, motor vehicle, and burn), and includes both intentional and unintentional injuries. An important part of the public health mission is to emphasize that injuries are preventable and to dispel the misconception that injuries are unavoidable.

Recognizing the need for more comprehensive injury surveillance data, the State and Territorial Injury Prevention Directors' Association (STIPDA) produced *Consensus Recommendations for Injury Surveillance in State Health Departments* in 1999.² These recommendations were developed by a working group representing STIPDA; the Council of State and Territorial Epidemiologists (CSTE); Centers for Disease Control and Prevention (CDC) and its National Center for Injury Prevention and Control (NCIPC); and the National Association of Injury Control Research Centers (NAICRC).

Consensus Recommendations identifies 14 specific injuries and injury risk factors to be placed under surveillance by all states and 11 data sets to monitor these injuries and risk factors. The goal is to improve state-based injury surveillance to better support injury prevention programs and policies. By enhancing and standardizing injury surveillance at the state level, its integration with overall public health surveillance as part of the National Public Health Surveillance System (NPHSS)³ will be much easier. In tandem with the *Consensus Recommendations*, CSTE and STIPDA developed injury indicators that were formally adopted for inclusion in NPHSS.^{4,5} The NPHSS injury indicators add to other indicators developed by CSTE for chronic diseases and other areas.⁴

What is an Injury Indicator?

An injury indicator describes a health outcome of an injury, such as hospitalization or death, or a factor known to be associated with an injury, such as risk or protective factor among a specified population.

Methods

Because injury rates often vary dramatically by sex, overall age-adjusted rates for hospitalization and fatal indicators were calculated as the weighted average of the male and female rates for each indicator:

$$\text{Overall Rate} = \frac{\left[\begin{array}{c} \text{Age-Adjusted} \\ \text{Male} \\ \text{Rate} \end{array} \times \begin{array}{c} \text{Male} \\ \text{Population} \end{array} \right] + \left[\begin{array}{c} \text{Age-Adjusted} \\ \text{Female} \\ \text{Rate} \end{array} \times \begin{array}{c} \text{Female} \\ \text{Population} \end{array} \right]}{\text{Male Population} + \text{Female Population}}$$

However, in low-incidence indicators, it was not always possible to calculate a stable rate for females. In these cases, the overall age-adjusted rate was calculated using the sum of the male and female cases and the sum of the male and female populations by age within the state.

Participating states reported on 12 of the 14 injuries and risk factors in *Consensus Recommendations*:

- motor vehicle injuries,
- alcohol involvement in motor vehicle deaths,
- self-reported seat belt and child safety seat use,
- homicide,
- suicide,
- suicide attempts,
- firearm injuries,
- traumatic brain injuries,
- fire and burn injuries,
- self-reported smoke alarm use,
- submersion injuries,
- poisoning.

For some of these conditions and risk factors, multiple sources of surveillance data are recommended; therefore, two or more surveillance indicators are used.

Two conditions in *Consensus Recommendations* are not reported here: traumatic spinal cord injuries and injuries from falls. Surveillance case definitions and recommendations for data sources are not yet final for these injuries. STIPDA is convening its fourth Injury Surveillance Workgroup to develop case definitions for these remaining injuries.

States used a total of five data sets to report on 21 indicators: the Fatality Analysis Reporting System (FARS), the state-based Youth Risk Behavior Survey (YRBS), the Behavioral Risk Factor Surveillance System (BRFSS), state vital records, and state hospital discharge data (HDD).

Fatality Analysis Reporting System (FARS)

FARS, coordinated by the National Highway Traffic Safety Administration (NHTSA), contains data on all fatal traffic crashes that occur in the 50 states, the District of Columbia, and Puerto Rico. To be included in FARS, a crash must involve a motor vehicle traveling on a public roadway and result in the death of a person (either a vehicle occupant or a non-motorist) within 30 days of the crash. The FARS file contains a description of each fatal crash reported. More than 100 coded data elements characterize each crash, the vehicles, and the people involved. NHTSA considers a fatal motor-vehicle crash to be alcohol-related if either a driver or non-occupant (e.g., pedestrian or bicyclist) had a blood alcohol concentration (BAC) greater than or equal to 0.01 g/dL.⁶

FARS does not include non-traffic crashes, such as those occurring on driveways and other private property. It also does not include deaths occurring more than 30 days after the motor vehicle crash. Because BACs are not available for all persons involved in fatal crashes, NHTSA's estimates for the number of alcohol-related traffic fatalities are based on a discriminant analysis of information from all cases for which driver or non-occupant BAC data are available.⁶

Youth Risk Behavior Survey (YRBS)

YRBS, a component of the Youth Risk Behavior Surveillance System, is managed by the National Center for Chronic Disease Prevention and Health Promotion (NCCDPHP) at CDC. It is a self-administered, school-based survey conducted biennially in many locations throughout the country among ninth through twelfth-grade students. State and local departments of education and health conduct the survey, and CDC analyzes the data. The YRBS monitors risk behaviors associated with the leading causes of injury and death among teenagers.⁷

YRBS data apply only to youth who attend school. In addition, the extent of underreporting or overreporting of behaviors cannot be determined, although the survey questions demonstrate good test-retest reliability. Interstate comparisons must be interpreted cautiously as methods used to collect YRBS data may vary.⁷

Among the 26 states included in this report, 11 conducted a YRBS in 1999 with overall participation rates of at least 60%. CDC requires a minimum overall participation rate of 60% to generalize a state's population. This report presents weighted data from these 11 states.

Behavioral Risk Factor Surveillance System (BRFSS)

CDC's National Center for Chronic Disease Prevention and Health Promotion also manages the BRFSS. This is a broader ongoing survey. It is a state-based, random-digit-dialed telephone survey of the noninstitutionalized U.S. population over age 17. BRFSS monitors risk behaviors associated with the leading causes of disease, injury, and death.⁸

Because BRFSS is telephone-based, population subgroups less likely to have telephones, such as persons of low socioeconomic status, may be underrepresented. In addition, data are self-reported and may be biased. For risk-reduction factors such as self-reported use or testing of smoke detectors, these data may not uniformly represent safe and effective use.⁸

State Vital Records

Death registration is the responsibility of individual states. The funeral director and the physician who certifies the cause of death are usually responsible for the personal and medical information recorded on the death certificate. The cause-of-death section on the certificate is basically the same in all states, and is organized according to World Health Organization (WHO) guidelines. Local registrars assure that all deaths in their jurisdictions are registered and that required information is on death certificates before sending them to the state registrar. State registrars number and file the death certificates; certificates of nonresidents are sent to their states of residence. All states send death certificate data to the National Vital Statistics System, managed by CDC's National Center for Health Statistics.⁹

Data are limited to what is reported on death certificates. The degree of detail in reporting varies among jurisdictions. In general, death certificate data provide limited information about circumstances of injury incidents or contributing factors. Deaths associated with some injuries, especially suicide, may be underreported.

The number and type of cause-of-death fields to which states have access also vary. Two of the states contributing to this report had access to a death certificate database listing only the *underlying* cause of death. In contrast, the other 24 states each had access to a database listing both *underlying* cause of death and *contributing* causes of death. States without access to multiple contributing cause-of-death fields cannot calculate fatality rates for traumatic brain injury (TBI) because the diagnostic codes that make up that case definition reside in the contributing cause-of-death fields.

In 1999, a new classification scheme—the Tenth Revision of the *International Classification of Diseases* (ICD-10)—was implemented in the United States. The Ninth Revision of the ICD (ICD-9), had been in use from 1979 through 1998. The ICD has been revised about every ten years since 1900. The purpose of revisions is to stay abreast of medical advances in terms of disease and injury nomenclature and etiology.¹⁰ ICD-10 differs from ICD-9 in several respects. ICD-10 is more detailed, containing 8,000 categories compared with only 5,000 categories in ICD-9. ICD-10 uses alphanumeric codes compared with numeric codes in ICD-9. Some additions and modifications were made to the chapters in the ICD. Some of the coding rules and rules for selecting the underlying cause of death have also been changed.¹⁰ These changes create a discontinuity in cause-of-death statistics between 1979–1998 and those from 1999 forward.

The CDC’s National Center for Health Statistics (NCHS) is carrying out comparability studies to measure the effects of the newly revised ICD on the comparability with the previous revision of mortality statistics by cause of death.¹⁰ These studies involve the dual classification of a single year’s mortality data, i.e., classifying the underlying cause of death on mortality records by both the new revision and the previous revision. The key element of a comparability study is the comparability ratio, which is derived from the dual classification. It is calculated by dividing the number of deaths classified by the new revision by the number of deaths classified by the previous revision. The resulting ratios represent the net effect of the new revision on cause-of-death statistics. NCHS has released preliminary estimates of comparability ratios using the “List of 113 Selected Causes of Death” (113-cause list). The number 113 refers to the number of mutually-exclusive categories in the list. The 113-cause list actually contains a total of 135 cause-of-death categories, including accidents (unintentional injuries), intentional self-harm (suicide), and assault (homicide).

Preliminary results show comparability ratios for intentional self-harm and assault (homicide) are very close to 1.0. For unintentional injuries, a comparability ratio of 1.0303 indicates an increase in death rates of 3% due to the revisions. Virtually all of this increase involves shifts from natural causes in ICD-9 to unintentional injuries in ICD-10 resulting from changes in coding rules that assign injury as unintentional injury. Within the category unintentional injury, motor vehicle crashes (MVC) deserve special attention. The preliminary MVC comparability ratio was 0.8527. The reason for this 15% decrease is that in ICD-10, the injury must involve a “motor” vehicle. In ICD-9, in the absence of

the term “motor” when a vehicle crash was reported as occurring on a highway or road, the *assumption* was to classify the crash as involving a motor vehicle. The ICD-10 convention does not allow this assumption and classifies such crashes as involving unspecified vehicles (other land transport accidents). However, for U.S. data, it has been decided that if the crash occurred on a highway or road, classification to motor vehicle accident is appropriate. This change in classification was effective in the United States with the release of preliminary NCHS 1999 mortality data and results in a revised comparability ratio of 0.9754. This ratio is only applicable to data in which the classification change for motor vehicle crashes was implemented.¹⁰ **Some states’ final death files do not include this change. For this reason, motor vehicle crash deaths are not reported as a 1999 indicator. Since all the indicators are calculated from state databases, the rates would not be comparable.**

In this report, only one state—Arizona—did not implement ICD-10 for 1999 death data. Since the rates for Arizona, based on ICD-9, are not directly comparable to the rates reported by the other 25 states, death rates for Arizona are not displayed for 1999.

Comparability ratios can be used as factors to adjust mortality statistics for cause of death classified by ICD-9 to be comparable to rates for the same causes classified by ICD-10. **The ICD-10 mortality rates displayed in the *State Injury Indicators Report, Second Edition — 1999 Data* should not be compared directly to those displayed in the first *State Injury Indicators Report*, which displayed 1997 and 1998 mortality rates based on ICD-9.** The preliminary comparability ratios published by NCHS can be applied to the mortality indicators only for those conditions in which the

code groupings are exactly the same in both the 113-cause list and the fatal indicator definition (fatal fire-related injuries, homicide, and suicide).

State Hospital Discharge Data (HDD)

More than half of all states maintain databases of hospital discharge records for all non-federal, acute care hospitals within their borders.¹¹ The information collected varies from state to state. Many states use the standard uniform billing form (UB-92) as the basis for their hospital discharge database. Some states use only a subset of variables from the UB-92 for their databases, while a few collect additional variables.

The UB-92, developed by the National Uniform Billing Committee, includes the following data elements:

- patient’s age,
- sex,
- zip code,
- admission date,
- length of stay,
- total charges,
- principal diagnosis,
- up to eight additional diagnoses.

For diagnoses resulting from injuries, external cause of injury (E-code) is also coded. E-codes, which are listed in the *International Classification of Diseases-9 Clinical Modification* (ICD-9 CM) describe several aspects of an injury: intentionality; mechanism; and, for unintentional causes of injury, location of occurrence.¹²

Although HDD have been collected in some states for many years, their use for public health surveillance has been limited. HDD indicators for injury are based on a case definition that is being used for only the second time by multiple states. Each state reports comparable information about injury hospitalizations. Thus, the strengths and limitations of the case definition and data are not yet well-characterized. Several caveats should be noted:

- The data are generated from forms used to bill for hospital services. Quality assurance practices for these data vary from state to state.
- Not all states mandate that hospitals report HDD. Even in those that do, participation rates and requirements vary regarding the data elements to be reported, including the reporting of E-codes. It is difficult to determine the hospital participation rate in HDD collection because the total number of hospitals changes often, as they merge or close and new ones open.
- Among the states in this report, there is wide variation in coding percentages for E-coding for injury-related diagnoses; completeness ranges from 53% to 100%. Incomplete external cause coding not only leads to low rates of injury, but it can also introduce bias. Currently, there are few studies to indicate whether the underestimates presented here are biased.
- The percentage of E-coding for injury hospitalizations is increasing in many states. When comparing hospitalization rates within one state over several years or between states in the same year, it is critical to take into account the percentage of E-coding for

each year. Many states will have a factitious increase in injury hospitalization rates as their percentage of E-coding increases.

- A person might be counted more than once for one event, as with intra-hospital transfers between services. While many states have developed probability algorithms to eliminate such duplications, these algorithms differ, limiting comparability. Therefore, states contributing to this report were asked to leave suspected duplicates in the data set for this analysis. The rates displayed in this report reflect *numbers of hospitalizations*, rather than *numbers of people hospitalized*. The exceptions to this are California and Michigan, where HDD are generated in such a way that duplicate admissions were not available for inclusion in the analysis.
- Unlike the system for death certificates, no standard system exists to forward hospitalization data on nonresidents to their states of residence. This is a particular problem when trauma centers or other referral centers are just across state borders; injured residents may be hospitalized in the neighboring state without any record of their hospitalizations entering the HDD of their state of residence.

To remind readers of the limitations of HDD and to assist in the interpretation of HDD-based indicators, the first figure displaying rates calculated from HDD in each section of this report includes a section entitled “Factors Affecting Representativeness of State Hospital Discharge Data Sets for Injury Surveillance.” This section of the first figure displays the percentage of hospitalizations with E-codes, if the state includes readmissions, if they are impacted by cross-border

hospitalizations, and for the completeness of hospital participation. As the use of HDD for injury surveillance has developed only recently, this table will be included with any figure displaying rates calculated from HDD.

Future Efforts

The *State Injury Indicators Report, Second Edition — 1999 Data* represents great progress in standardizing state-based injury surveillance reporting. Participation has grown from 12 to 26 states. The report includes 12 of the 14 injuries and injury risk factors recommended for surveillance in *Consensus Recommendations*. Future reports should include all 14, once case definitions have been developed for surveillance of traumatic spinal cord injuries and falls. This report displays death and hospitalization rates by sex and age, which provide more detail for identifying populations at risk. States participating in this report look forward to refining current indicators and defining new ones, as we learn from the experience of producing each *State Injury Indicators Report*.

The data contained in this report are readily available in most states through national surveillance systems such as FARS, or through analysis of state data sets, such as death certificates or HDD. We expect the proportion of states represented in subsequent reports to increase as state injury surveillance systems become more comprehensive.

1. All-Injury Indicators

Surveillance of injuries resulting in hospitalization provides an important perspective on the public health burden of injury morbidity. National surveillance for hospitalizations is based on analysis of the National Hospital Discharge Survey, a national probability sample of hospital inpatient records.¹ In 2000, there were 1.8 million injury-related discharges from short-stay hospitals, accounting for an estimated 6% of all hospitalizations.²

Injury hospitalization rates for males and females are similar for all ages combined, but differ considerably within certain age groups. For ages 15 to 24 years, the injury hospitalization rate for males is 3.3 times that for females; for the elderly ages 75 years or older, the rate for females is 1.8 times that for males.²

The rates for all-injury hospitalizations displayed here represent hospitalizations when the principal diagnosis was an injury as defined by the inclusion criteria in the appendix. As the inclusion criteria are based on the nature of injury codes only, the percentage of external cause coding in a state's hospital discharge data (HDD) does not affect this rate. State rates for HDD-based indicators are affected by the percentage of hospitalizations with external cause coding, the inclusion of readmissions, the impact of cross-border hospitalizations, and the completeness of hospital participation. Figure 1a contains the section entitled, "Factors Affecting Representativeness of State Hospital Discharge Data Sets for Injury Surveillance" to be used when interpreting the accompanying rates.

Two other factors should be considered when interpreting HDD-based indicators. First, rates represent the number of hospitalizations per 100,000 population, *not* patients per 100,000 population. This is because individuals could have multiple hospital stays during the year, and there is no way to separately identify them. Second, since a small overlap with fatal injury indicators likely exists, this report displays hospitalization rates that include deaths occurring during a hospitalization for injury.

2. Traumatic Brain Injury Indicators (TBI)

Of all types of injury, TBI is among the most likely to cause death or permanent disability.¹ Each year in the United States, an estimated one million people are treated for TBI and released from hospital emergency departments;² 230,000 people are hospitalized for TBI and survive,³ and 50,000 people die.⁴ An estimated 5.3 million Americans live with a TBI-related disability.⁵

The risk of TBI is highest among adolescents, young adults, and people ages 75 years and older. Motor vehicle crashes, violence, and falls are the leading causes of TBI. Among people ages 65 years and older, falls are the leading cause of TBI. Motor vehicle crashes are the leading cause among persons ages 5 to 64 years. For persons of all ages, the risk of TBI among males is twice that among females. The outcome of these injuries varies greatly depending on the cause: 91% of firearm-related TBIs result in death, and 11% of fall-related TBIs are fatal.⁶

Nearly two-thirds of firearm-related TBIs are classified as suicidal intent.⁵ In 1990, firearms surpassed motor vehicles as the largest single cause of death associated with TBI in the United States.⁷ These data reflect the success of efforts to prevent TBI due to motor vehicle crashes and the failure to prevent such injuries due to firearms.¹ Continued surveillance of TBI is needed to monitor trends, identify high risk groups, prioritize prevention efforts, and to assess prevention programs.

Figures 2a, 2b, and 2c present TBI-related hospitalization rates in the 22 states in 1999; the range from lowest to highest rates was almost five-fold. Figures 2d, 2e, and 2f present the fatal TBI data in 21 states for the same year.

Figure 2d illustrates a more than three-fold difference between the lowest and highest rates. The ratio of hospitalized cases to death certificate-identified cases ranges from 1.4:1 to 7.6:1. As noted previously, cases of injury resulting in hospitalization and subsequent death may be included in both HDD and death certificate data. Males have higher rates of death and hospitalization than females. The highest rates of TBI death and hospitalization are seen among persons ages 65 years and older. (Table 2c and 2f.)

Limitation: The case inclusion criteria for TBI hospitalization in this report requires that an *injury* be listed in the principal diagnostic field and a TBI diagnosis in any diagnostic field. In contrast, the hospital-based CDC TBI surveillance definition requires that a TBI be listed in *any* of the diagnostic fields. Hospitalization rates based on CDC's TBI surveillance definition will be higher than the TBI hospitalizations indicators shown here.^{8,9} The TBI fatal indicator uses the same definition as the death file-based CDC TBI surveillance definition, so the death rates should be similar. Four states did not have access to state multiple cause-of-death files and so were not able to calculate the fatal TBI indicator.

3. Drowning Indicators

Drowning is the second leading cause of injury death among U.S. children ages 1 to 14 years. It is also in the top 10 causes of injury death for all ages. In 2000, 4,073 drownings occurred in the United States, the majority of which were unintentional (85.5%); 8.8% were intentional; 5.7% were undetermined.¹ Men are at higher risk than women (4:1), and blacks are at a higher risk than whites (1.4:1).²

Nationally, drowning rates are highest for two age groups: children under five years of age, and persons 15 to 19 years of age. In one California study, for every child who drowned another 4 were hospitalized, and 16 received emergency department care for near drowning.³ Near drowning can be costly and can result in lifelong disability.

Among adolescents and adults, risk factors for drowning include drinking alcohol, swimming alone, and not wearing a personal flotation device while engaged in water sports or recreation. For children under five, unexpected access to water or brief lapses in adult supervision are implicated in most drowning incidents.⁴

Infants commonly drown in bathtubs. As these young children become more mobile, small water containers such as buckets and toilets also pose drowning risks. Most toddlers and preschoolers drown in residential backyard pools. The percentage of drowning in open water such as lakes, rivers, and the ocean increases with age.⁵

Despite technological advancements in medical care, hospital treatment often does little to change the outcome of a submersion injury. Prevention is key, since the window

of opportunity to prevent brain damage or death is so small. Strategies to prevent drownings among infants and children focus on environmental changes:

- proper fencing of home pools,
- drainage of buckets,
- close supervision of children in bathtubs,
- public education and training in CPR.

Figures 3a, 3b, and 3c, which present the near drowning hospitalization data for 22 states in 1999, illustrate an eight-and-a-half fold difference between the lowest and highest hospitalization rates. In four states, the number of drowning hospitalizations was too low to calculate a stable rate. Figures 3d, 3e, and 3f present the drowning death data for 25 states in 1999. This figure shows over a four-fold difference between the lowest and highest rates. In three states, the number of drowning deaths in 1999 was too low to calculate a stable rate. Exposure to aquatic environments also varies by state and should be considered along with these rate differences.

In states where data are available by sex, males have higher rates of death and hospitalization than females. The highest death rates by age group are among 1 to 4 year olds, but events are infrequent and only states with large populations (California, Florida, and Texas) were able to calculate stable rates for this age group. Nine states showed relatively high death rates for 15 to 24 year olds. The highest hospitalization rates were among 1 to 4 year olds, followed by 5 to 14 year olds, consistent with the 1990 study cited earlier.³

The ratio of death versus hospitalizations for near-drowning ranges from 1:0.4 to 1:1.7. Similar ratios were reported in the previous *State Injury Indicators Report* using 1997 and 1998 data. Hospitalization for submersion injuries appears to be a more common outcome among children 14 years old and under than it is for adults.

4. Fire-Related Indicators

The United States has the fourth highest overall fire death rate of all industrialized countries.¹ Residential fires cause about 85% of all civilian fire-related deaths.² In 2000, 379,500 residential fires in the United States claimed the lives of 3,445 people and injured another 17,400.² Cooking is the leading cause of home fires,² while smoking-related fires are the leading cause of home fire deaths.³

Residential fires disproportionately affect young children, older adults, African-Americans, and Native Americans. The southern region of the United States has the highest fire death rate. Contributing factors may include rural poverty, a lower prevalence of functional smoke alarms, and a greater use of portable heating equipment.⁴

Working smoke alarms reduce the chance of dying in a house fire by 40% to 50%.⁵ One large-scale smoke alarm giveaway program reduced the incidence of fire-related injury rates by 80% in its target area.⁴ However, about 25% of U.S. households lack working smoke alarms.⁶

Figures 4a, 4b, and 4c represent the 1999 combined residential and non-residential fire-related hospitalization data for 22 states. There were too few hospitalizations in three states to calculate stable rates and four states did not provide hospitalization data. Reported fire-related hospitalization rates ranged from 2.2 per 100,000 population to 7.4 per 100,000 population.

Figures 4d, 4e, and 4f represent the 1999 combined residential and non-residential fire-related fatality data for 25 states. For seven states, there were too few deaths to

calculate stable rates and one state did not provide data on fatalities. The reported fire-related fatality rates ranged from 0.7 per 100,000 population to 2.4 per 100,000 population.

Fire-related hospitalization rates were 1.3 to 6.6 times higher than the death rate among the states reporting both rates. Males had higher rates than females for both deaths and hospitalizations. Age-specific rates of fire-related fatalities and hospitalizations could not be calculated for many of the age categories because of small numbers. When rates could be calculated, they tended to be highest among adults 75 years of age and older and among children ages one to four years.

Figure 4g represents the percentage of homes in which all the smoke alarms had been tested within the past month, as is currently recommended,⁵ for 25 states. The proportion of these homes ranged from 21.7% (Minnesota) to 42.4% (Oklahoma). In 1999, 33.5% of U.S. homeowners reported that they tested all their smoke alarms within the past month.⁷ Only nine of the 25 states had a proportion higher than the national average.

Figure 4h presents the percentage of homes without smoke alarms in 25 states. The proportion of homes lacking any smoke alarms ranged from 1.3% (Oregon) to 13.0% (Hawaii). Nationally, 3.9% of U.S. homes had no smoke alarms in 1999.⁷ Of the 25 states, 13 had a higher percentage of homes without a smoke alarm than the national average.

5. Motor Vehicle Indicators

In 1999, motor vehicle crashes (MVCs) were the cause of more than 42,000 deaths¹ and more than four million emergency department visits.² Among persons ages 1 to 34, MVC injuries are the leading cause of death in the United States.¹ In all age groups, MVC injuries are the leading cause of years of potential life lost (YPLL) and deaths from unintentional injuries.¹

Alcohol-impaired driving increases the risk of death and is a *major* public health concern in the United States. In 1999, 38% of traffic fatalities were alcohol-related; either the driver or an affected person (e.g., a pedestrian or a bicyclist) had a blood alcohol concentration of at least 0.01 g/dL.³ In 1993, about 1.5 million arrests were made for impaired driving. That same year there were over 120 million episodes of alcohol-impaired driving among adults in the United States; nearly 10 million of these episodes involved underage youth 18 to 20 years of age.⁴

Failure to use a safety belt or child restraint is another major risk factor for fatalities and injuries to motor vehicle occupants. It is estimated that among front seat occupants, lap/shoulder belt use reduces the risk for fatal injury by approximately 45% and the risk for moderate to critical injury by 45% to 50%. Child safety seat use reduces the likelihood of fatal injury by an estimated 71% for infants and 54% for toddlers.³

For 1999 only, MVC fatalities are not displayed because they would not be comparable among states. As mentioned in the Methods section of the Introduction, the change from

ICD-9 to ICD-10 coding for death data produced an artificial change in rates for certain conditions. In the comparability study performed by the National Center for Health Statistics (NCHS), the rate for MVC-related deaths appeared lower when ICD-10 coding was used. The initial comparability ratio was 0.8527. The reason for this 15% decrease was that, in ICD-10, it must be explicit that the injury involved a “motor” vehicle. In ICD-9, in the absence of the term “motor” or when a vehicle crash was reported as occurring on a highway or road, the assumption was to classify the crash as involving a motor vehicle. The ICD-10 convention does not allow this assumption and classifies such crashes as involving unspecified vehicles. However, as a result of previously mentioned initial results, NCHS decided that, for U.S. data, if the crash occurred on a highway or road, classification to MVC is appropriate.⁵ While this adjustment was made to the 1999 national data set, and NCHS recommended these adjustments to all state and territorial Vital Registrars for state death data sets, some states elected not to re-open their 1999 death files to make this adjustment. As this report used state-based data sets, there would have been an artificial variation in rates among states of 15%, confusing the true picture. To view state MVC death rates calculated from the corrected national death data files, go to the WISQARS website.¹

Figures 5a, 5b, and 5c present data from 22 states on hospitalizations for MVC. The rate varied almost 2.6 times from the lowest state rate (43.4 per 100,000) to the highest (110.5 per 100,000). Rates are higher for males than females,

and the highest rates are generally found among 15 to 24 year olds, and those over 75 years of age. Overall, MVC hospitalizations occur at three to eight times the rate of MVC deaths (calculated from the national death data files).

Information about two motor vehicle-related risk behaviors are available for 1999, “driving after perhaps having too much to drink” is available from the Behavioral Risk Factor Surveillance System (BRFSS), and “high school students reporting always using safety belts” from the Youth Risk Behavior Survey (YRBS). Questions about seat belt use were not asked on the BRFSS questionnaires in 1999. Figures 5d, 5e, and 5f present data showing that between 2.6% and 9% of adults in the participating states reported driving after perhaps having had too much to drink in the past month. Figures 5g and 5h present data on self-reported safety belt use among high school students (YRBS) in 1999. The highest reported use of safety belts in high school students was 50.5%. In all but four of the 14 states with weighted YRBS data, fewer than 40% of high school students reported using safety belts. Males reported a higher rate of both risk behaviors than females.

6. Poisoning Indicators

Poisoning is the damaging effect of exposure to a broad range of chemicals (e.g., gases, pesticides, heavy metals, drugs, and a variety of common household substances such as bleach and ammonia). In 1999, 19,741 people died from poisoning in the United States.¹ Drug overdoses, specifically misuse of medications and recreational drugs, caused about three-fourths of these deaths.² Nationally, over 60% of poisonings nationally in 1999 were unintentional, 25% were suicides, less than 1% were homicides, and 13% were of undetermined intent.¹ Rates of poisoning by suicide and homicide have not increased in the past decade. In contrast, the rates of unintentional poisoning deaths and poisoning deaths with undetermined intent have increased since 1990.²

Males have more than two times the risk for poisoning death compared to females. The largest difference is in the category of unintentional poisoning death, where mortality rates among men are more than three times that of women. In suicide poisoning deaths, males have about one and a half times the rate of females. Blacks have the highest mortality from all poisoning (B:W 1.2:1), unintentional poisoning (B:W 1.7:1), and undetermined poisoning (B:W 1.6:1). In suicide poisoning, blacks have lower rates than whites (B:W 1:3.1). Asian American/Pacific Islanders had the lowest rates of poisoning in all categories. Most poisoning deaths (84%) occur among people ages 25 to 54. Poisoning deaths in children under the age of five account for only 0.4% of all poisoning mortality.¹ Since 1960, poisoning deaths of children younger than five years have decreased dramatically. A steep decline occurred after childproof packaging was required on all drugs and medications beginning in 1973.³

Figures 6a, 6b, and 6c present the poisoning-related hospitalization data for 21 states in 1999. Figure 6a illustrates a more than two-fold difference between the lowest and highest rates. Figures 6d, 6e, and 6f present the poisoning death rates for 25 states in 1999. Figure 6d shows a four-and-one-half-fold difference between the lowest and highest rates. Overall, individual state hospitalization rates were four to fifteen times higher than death rates for poisoning-related injuries. Males had higher rates than females in poisoning deaths, while females had higher rates of hospitalization. The highest poisoning mortality rates were among people 35 to 54 years of age. Age-specific rates could not be calculated for many age categories due to small numbers.

7. Firearm-Related Indicators

Firearm-related injuries are the second leading cause of injury-related death in the United States, accounting for approximately 29,000 deaths in 1999.¹

Both fatal and nonfatal firearm-related injury rates are highest among persons ages 15 to 24 years; black males in that age group have the highest risk. Fatal and nonfatal firearm-related injury rates for Hispanics are generally less than those for blacks, but higher than those for white non-Hispanics. Nationally, the firearm-related death rate for males is six times higher than that of females; the nonfatal firearm-related injury rate for males is eight times higher. The proportion of persons who die from firearm-related injuries increases with age. Of those who survive a gunshot wound and are treated in a hospital emergency department (ED), approximately 55% are hospitalized or transferred, and the other 45% are treated and released. Nationally, the case-fatality rate and hospitalization rate is higher for firearm-related injuries than for any other cause of injury.² This means that a person is more likely to die or be hospitalized for a firearm-related injury than any other injury.

The majority of fatal and nonfatal firearm-related injuries among teenagers and young adults result from violence. In contrast, firearm-related injuries among older adults are predominantly self-inflicted. Although unintentional firearm-related deaths represent less than 4% of all firearm deaths, approximately one-fifth of non-fatal firearm-related injuries treated in U.S. hospital EDs are unintentional.²

In 1994, treatment of gunshot injuries in the United States cost an estimated \$2.3 billion in lifetime medical costs, of which \$1.1 billion was paid by the federal government.³

Nationally, fatal firearm-related injury rates declined 29%, and nonfatal firearm-related injury rates declined 47% during 1993-1998.¹ Although the reasons for these changes are unknown, certain factors may have contributed to the decrease. For example, the decline in assault firearm injuries is consistent with a 27% decrease in violent crime⁴ and a 20% decline in non-firearm homicides during the same period.¹ Possible contributors include improvements in economic conditions; aging of the population; decline of the cocaine market; changes in legislation, sentencing guidelines, and law-enforcement practices; and violence prevention programs.⁵ However, the importance and relative contribution of each of these factors have not been determined.

Figures 7a, 7b, and 7c represent firearm-related hospitalization data submitted by 22 states for 1999. In two states, the number of hospitalization cases was too small to allow calculation of a stable rate. There is an approximately five-fold difference between the lowest and highest rates for hospitalization. Figures 7d, 7e, and 7f represent firearm-related death rates in 25 states in 1999, and illustrate more than a six-fold difference between the lowest and highest rates. In almost all states, the highest rates of firearm death are seen among people ages 15 to 34 years, with a second peak among those over 75. For hospitalizations, the highest rates again are found among those ages 15 to 34 years, but

there is no second peak in the oldest age group. This is probably because fire-arm injuries among the elderly are often self-inflicted and usually lethal. The ratio of hospitalization to death ranges from 0.3:1 to 1.1:1. Firearm fatality and hospitalization rates are much higher for males than females.

8. Homicide Indicators

Homicide is the fourteenth leading cause of death overall in the United States, and it is the second most common cause of death among people ages 15 to 24 years. In 1999, 16,889 people were killed in homicides. Firearms were used in 64.1% of these homicides. The next most commonly reported mechanism (11.1%), was cutting and stabbing with sharp instruments, such as knives.¹

Figure 8a presents the homicide data for 25 states in 1999 and illustrates a more than four-fold difference between the lowest and highest rates. Males are three times more likely than females (Figure 8b) to die from homicide. The highest rates are seen among people ages 15 to 34 years (Figure 8c).

Black males ages 20 to 24 have the highest homicide rate of any group in the United States: 110.6 per 100,000 in 1999.¹ Homicide rates are lowest for Asian Americans, with whites having only slightly higher rates. Rates for Native Americans are three times higher than those of Asian Americans, and rates for blacks are more than six times higher than those of Asian Americans.¹

Homicide rates are higher in the southern United States than in the northern part of the country, and rates in metropolitan areas are higher than elsewhere. Homicide is associated with high urbanization and socioeconomic deprivation.² These factors are thought to underlie the observed variation in risk by race.

9. Suicide Indicators

Suicide is a major public health problem in the United States, claiming the lives of approximately 30,000 people each year.¹ In 1999 and 2000, suicide was the 11th leading cause of death overall in the United States, the second leading cause of death among adults ages 25 to 34 years, and the third leading cause of death for adolescents and young adults ages 15 to 24 years.² Although suicide rates are highest among persons age 65 and older,¹ the rate of suicide among adolescents and young adults nearly tripled between 1952 and 1994.¹ Overall, males are four times more likely than females to die from suicide.¹ In addition to the human toll, the economic costs of suicide are enormous. One study estimated the total economic burden of suicide in the United States to be \$111.3 billion in 1995.³

Completed suicides are not the only public health concern. Suicidal ideation, planning, and attempts also have a major public health impact. In 1999, there were an estimated 671,000 hospital emergency department visits for suicide attempts in the United States.⁴ Because one of the strongest risk factors for suicide is a previous attempt, surveillance of such attempts can help identify high risk groups and target prevention strategies.⁵ The comparative epidemiology of suicidal ideation and behavior shows some important differences. For example, the suicide rate for males is higher than for females, but studies of suicidal thoughts and suicide attempts routinely show females with higher rates.⁵

Figures 9a, 9b, and 9c display suicide attempt injury hospitalization data in 21 states. Figures 9d, 9e, and 9f show suicide data from 25 states in 1999, illustrating a more than

two-fold difference between the lowest and highest rates. Hospitalization was 1.8 to 5.0 times more common than death. Males show a higher rate of suicide, while females have a higher rate of hospitalization for suicide attempts. Suicide attempts resulting in hospitalization, that did not have an injury coded in the principal diagnostic field, are not counted in the case definition for hospitalization for a suicide attempt. Therefore, not all hospitalizations related to suicide attempts are represented in these figures.

Figures 9g and 9h present Youth Risk Behavior Survey data on self-reported suicide attempts among high school students in 14 states. Female high school students report a higher rate of suicide attempts than males.

FIGURE 9g.
**Suicide Indicator: Percentage of High School Students Reporting
Suicide Attempt During Past 12 Months, 1999, Youth Risk Behavior Survey**

Note: No data available for Arizona, California, Colorado, Georgia, Kansas, Louisiana, Minnesota, North Carolina, Oklahoma, Oregon, Texas, and Washington.

FIGURE 9h.

Suicide Indicator: Percentage of High School Students Reporting Suicide Attempt During Past 12 Months by Sex, 1999, Youth Risk Behavior Survey

Note: No data available for Arizona, California, Colorado, Georgia, Kansas, Louisiana, Minnesota, North Carolina, Oklahoma, Oregon, Texas, and Washington.

Appendix – Instructions for Calculating National Public Health Surveillance System Indicators Using 1999 Data

Instructions referenced in this report were circulated to the states to help them prepare 1999 data. While the format for those instructions has been modified for presentation here, the content is the same.

Note: In the future, CDC will modify instructions based upon feedback received. Instructions for calculating the National Public Health Surveillance System (NPHSS) indicators will be modified as appropriate in subsequent data collection cycles.

Computation of Rates

- Compute rates per 100,000 population.
- Use the estimated population for the year of the data. Obtain that estimate from your state's demographic center or from:
www.census.gov/population/
<http://eire.census.gov/popest/estimates.php>
- Round rates to one decimal place.

Data Source: Death Certificates

Mortality indicators should be age-adjusted to the 2000 standard using CDC's National Center for Health Statistics (NCHS) population distribution (Table 1). Calculate age-adjusted rates for both the male and female populations.

- With the exception of the fatal TBI indicator, all fatal indicators should be calculated by searching the *underlying cause of death field only*. For the fatal TBI indicator, search *all fields* in a multiple cause of death file.
- Count deaths of state residents only.
- For each indicator, report the age-adjusted rates stratified by sex (female and male), and report the overall age-adjusted rate for the state as the weighted average of the age-adjusted male and female rates as follows:

$$\text{Overall Rate} = \frac{\left[\begin{array}{c} \text{Age-} \\ \text{Adjusted} \\ \text{Male} \\ \text{Rate} \end{array} \times \begin{array}{c} \text{Male} \\ \text{Population} \end{array} \right] + \left[\begin{array}{c} \text{Age-} \\ \text{Adjusted} \\ \text{Female} \\ \text{Rate} \end{array} \times \begin{array}{c} \text{Female} \\ \text{Population} \end{array} \right]}{\text{Male Population} + \text{Female Population}}$$

Report age-specific rates for each indicator in the following age categories:

Under 1	45–54
1–4	55–64
5–14	65–74
15–24	75–84
25–34	85+
35–44	

Indicators

Fatal TBI:

S01.0–S01.9, S02.0, S02.1, S02.3, S02.7–S02.9,
S06.0–S06.9, S07.0, S07.1, S07.8, S07.9, S09.7–S09.9,
T01.0, T02.0, T04.0, T06.0, T90.1, T90.2, T90.4,
T90.5, T90.8, T90.9

Drowning:

- (1) Unintentional: W65–W74
- (2) Water transport: V90, V92

Fatal Fire-Related Injuries:

X00–X09

Fatal Firearm Injuries:

W32–W34, X72–X74, X93–X95,
Y22–Y24, Y35.0

Homicide:

X85–Y09, Y87.1

Suicide:

X60–X84, Y87.0

Fatal Motor Vehicle Traffic injuries:

V30–V39 (.4–.9), V40–V49 (.4–.9), V50–V59 (.4–.9),
V60–V69 (.4–.9), V70–V79(.4–.9), V81.1, V82.1,
V83–V86 (.0–.3), V20–V28 (.3–.9), V29 (.4–.9),
V12–V14 (.3–.9), V19 (.4–.6), V02–V04 (.1, .9),
V09.2, V80 (.3–.5), V87 (.0–.8), V89.2

Poisoning:

X40–X49, X60–X69, X85–X90, Y10–Y19, Y35.2

Data Source: Hospital Discharge Data (HDD)

- Hospitalizations should be age-adjusted to the 2000 standard using NCHS population distribution (Table 1).
- Include only non-federal, acute care, or inpatient facilities in your HDD data set. This excludes VA and other federal hospitals, rehabilitation centers, and psychiatric hospitals.
- Include readmissions, transfers, and deaths occurring in the hospital.
- Count hospitalizations of state residents only.
- In order to calculate Injury Hospitalization Indicators, first you need to create a subset of hospital discharge records based on the principal diagnosis field. The subset you create will be injury hospitalizations, defined as follows.

- **Injury hospitalization:** Records in which the principal reason for admission, after study, to a non-federal, acute care, inpatient facility was an injury, including late effects, but excluding adverse effects of therapeutic use of drugs and adverse effects of medical/surgical care and the late effects of those adverse effects.

Instructions for Creating the Injury Hospitalizations Subset of a State Hospital Discharge Data Set

Search only the principal diagnostic code field for the included N-codes. Exclude all other records from the injury hospitalization subset.

Include	Exclude
305	< 305
518 (only if there is also a corresponding E-code of E830, E832, E910, E854, E864, or E884)	306–800 (with the exception of 518 as noted under “include”)
800–909.2	909.3
909.4	909.5
909.9–994.9	995.0–995.4
995.5–995.59	995.6–995.7
995.80–995.85	995.86, 995.89
	996–999

Once the injury hospitalization subset has been created, calculate the injury indicators defined below by searching for E-codes in the following manner: Search all diagnosis fields. If there is a designated E-code field in your data set, start with the designated E-code field. Count the first-listed valid E-code, unless it is E849, E967, E869.4, E870–879, or E930–949, in which case, search any additional E-code fields and all diagnostic fields and use the next listed valid E-code.

For each indicator, report the age-adjusted rates stratified by sex (female and male), and report the overall age-adjusted rate for the state as the weighted average of the age-adjusted male and female rates as follows:

$$\text{Overall Rate} = \frac{\left[\begin{array}{c} \text{Age-Adjusted} \\ \text{Male} \\ \text{Rate} \end{array} \times \begin{array}{c} \text{Male} \\ \text{Population} \end{array} \right] + \left[\begin{array}{c} \text{Age-Adjusted} \\ \text{Female} \\ \text{Rate} \end{array} \times \begin{array}{c} \text{Female} \\ \text{Population} \end{array} \right]}{\text{Male Population} + \text{Female Population}}$$

Report age-specific rates for each indicator in the following age categories:

Under 1	45–54
1–4	55–64
5–14	65–74
15–24	75–84
25–34	85+
35–44	

Indicators

Hospitalizations for Injury:

N-codes 800–909.2, 909.4, 909.9–994.9, 995.5–995.59, 995.80–995.85.

Search for N-code only in the principal diagnostic field.

The case count for hospitalizations for injury should be equivalent to the number of records in your injury hospitalization subset.

Hospitalizations for TBI:

N-codes 800.0–801.9, 803.0–804.9, 850.0–854.1, 959.01.

Search all diagnosis fields of the injury hospitalization subset.

Hospitalizations for Near Drowning:

N-code 994.1 and/or E-codes E830, E832, E910, E954, E964, or E984

Search all diagnosis fields for N-code.

Search for E-codes as described above.

Hospitalizations for Fire-Related injuries:

E-codes E890–E899

Hospitalizations for Firearm Injuries:

E-codes E922.0–E922.3, E922.9, E955.0–E955.4, E965.0–E965.4, E985.0–E985.4, or E970

Hospitalizations for Suicide Attempts:

E-codes E950–E959

Hospitalizations for Motor Vehicle Injuries:

E-codes E810–E825

E-codes E810–E819

Hospitalizations for Poisoning:

E-codes E850–E869, E950–E952, E962, E972, and E980–E982

Percentage of HDD Injury Hospitalizations with External Cause Coding:

$$\text{Percentage of HDD Injury Hospitalizations with External Cause Coding} = \frac{\text{All Hospital Discharge Records with Injury Principal Diagnosis and Associated E-code}}{\text{All Hospital Discharge Records with an Injury Principal Diagnosis}} \times 100$$

Number of records with principal diagnosis of ICD-9 CM 800–994, 995.5 and 995.80–995.85, excluding ICD-9 CM 909.3 and 909.5 that have a valid E-code other than E849, E967, E869.4, E870–879, or E930–949

Number of records with principal diagnosis of ICD-9 CM 800–994, 995.5 and 995.80–995.85, excluding ICD-9 CM 909.3 and 909.5

Note: Please submit rates for fatal and hospitalization indicators in the accompanying Excel spreadsheets to facilitate CDC's Injury Center compilation of the results.

Indicators based on BRFSS, YRBS, and FARS will be calculated at CDC and sent to participating state health departments for their review.

Data Source: Behavioral Risk Factor Surveillance System (BRFSS)

- Not all BRFSS questions are asked every year. In 1999, the only injury questions asked pertained to the indicators listed below.
- BRFSS indicators are at: www.cdc.gov/nccdphp
- Report percentage of respondents.
- **Percentage of Adults Reporting Driving after Perhaps Having Too Much to Drink, in the Past Month:** *How often have you driven after having perhaps too much to drink during the last 30 days?* Report percentage answering one or more times.

Data Source: Youth Risk Behavior Survey (YRBS)

- YRBS is a biennial survey.
- YRBS indicators should be reported as percentage of respondents.
- **Do not age adjust.**
- **Percentage of High School Students Reporting Suicide Attempt During Past 12 Months:** Report percentage of respondents answering one or more attempts.
- **Percentage of High School Students Reporting Always Using Safety Belts:** *How often do you wear a seatbelt when riding in a car driven by someone else?* Report percentage of respondents answering “Always”.

Data Source: Fatality Analysis Reporting System (FARS)

Alcohol-involved Motor Vehicle Crash (MVC) Deaths:

An alcohol-related crash death is defined as a death in a motor vehicle traffic crash where either the driver or nonoccupant (e.g., pedestrian) had a blood alcohol concentration (BAC) ≥ 0.01 g/dL in a police-reported traffic crash.

State-specific counts are published by National Highway Traffic Safety Administration (NHTSA) in the annual publication *Traffic Safety Facts*. To calculate the crude alcohol-involved MVC death rate, look up the count in Table 114 “Persons Killed, by State and Highest Blood Alcohol Concentration in the Crash.” The numerator for calculating this rate is in the column “Total Killed in Alcohol-Related Crashes.” Use the estimated state population for the year as the denominator. Using this method, it will not be possible to calculate age-adjusted rates, as age-specific counts are not provided in the tables.

Table 1. Age Adjustment Table
All Ages — Eleven Age Groups

Age	U.S. 2000 Standard Population (1,000's)	Adjustment Weights
All ages	274,634	1.000000
Under 1	3,795	0.013818
1-4	15,192	0.055317
5-14	39,977	0.145565
15-24	38,077	0.138646
25-34	37,233	0.135573
35-44	44,659	0.162613
45-54	37,030	0.134834
55-64	23,961	0.087247
65-74	18,136	0.066037
75-84	12,315	0.044842
85+	4,259	0.015508
